Abstract:

We investigate the intra-day effect of interventions in both the post- global crisis and pre-crisis periods by the Bank of Japan (BOJ) in foreign exchange markets using limit order data at intra-day high frequency. First, we find that the relationship between order flow and market return in dollar/yen exchange markets experiences a structural change following unexpected and very high volumes of offer/sell orders by BOJ interventions. Then, a simple methodology is proposed to detect the exact timing of interventions. Second, with the measured lifetime of limit orders, we find that volume, gap between quote and market price, and a slower pace of the market all contribute to a longer stay in the order book for a limit order, whereas large outstanding orders in the order book shorten the lifetime of a new limit order. Finally, we find interventions, detected by the proposed methodology, significantly reduce the life-time of limit order in the market.

Journal of Economic Literature Classification: F31 (foreign exchange), G12 (trading volume), G14 (information and market efficiency), G15 (international financial markets), E58 (central bank).

Keywords: the Bank of Japan; Central bank interventions; Foreign exchange market; Order flow.

1. Introduction

The foreign exchange market interventions by the Bank of Japan (BOJ) were both voluminous and frequent in 2003 and 2004. US dollars equivalent to 20,246.5 (2003) and 14,831.3 (2004) billion Japanese yen, were purchased on the yen/dollar exchange market over 82 (2003) and 47 (2004) trading days. However, after the last day of the BOJ intervention on March 16, 2004, the Ministry of Finance of Japan and the BOJ quietly observed the movements of the Japanese yen on foreign exchange markets despite the fact that the Japanese yen was experiencing its historically highest level of appreciation since the World War II.

At the beginning of 2007, the sub-prime housing market in the U.S. started plummeting, and the consequent financial turmoil spread to the rest of the world. The US dollar and Euro depreciated against the other major currencies, especially against the Japanese yen. After six years of inactivity, the BOJ intervened in the yen/dollar exchange market on September 15, 2010, to the surprise of many market participants¹. The size of the intervention transaction per day was unprecedentedly high, at 2,124.9 billion yen². This is equivalent of 25,601 (24,999) million US dollars, calculated at the rate of 83.0 (85.0) Japanese yen per US dollar.

In this paper, we investigate the effects of the BOJ intervention on September 15, 2010 on trading activities on the yen/dollar market of the Electronic Broking System (EBS). To determine whether the findings are specific to this event, i.e., the first time in six years and the first time after the global crisis, we also apply the same methodology to five intervention days during the pre-crisis period. The major two contributions of this investigation are the following: First, we find that the relationship between order flow and market return on the dollar/yen exchange market experiences a structural change following an unexpected and very high volume of offer/sell orders due to the BOJ intervention. Then, a simple methodology is proposed to detect the exact timing of

¹ Prior to September 15, 2010, Mr. Noda, then Minister of Finance, repeatedly spoke to the media saying that the MOF and the BOJ would take necessary actions, including interventions, to halt further appreciation of the Japanese yen against the US dollar. However, the market participants, as reported frequently in the media, did not believe that the MOF and the BOJ would intervene in the yen-dollar exchange market on this particular day. Mr. Noda revealed in a morning interview with the press on the same day that the MOF requested the intervention of the BOJ at 10:30 AM (1:30 in GMT).

² After this intervention, the BOJ intervened in the foreign exchange market to the amount of 692.5 billion Japanese yen on March 18, 2011 and (the historically highest amount per day) 4,512.9 billion Japanese yen on August 4, 2011. By the end of November, 2011, the Ministry of Finance reports that the total value of interventions between October 28 and November 28, 2011 was 9,916 billion Japanese yen.

interventions. The cumulative sum of the forecast residuals from this return-volume regression is useful in detecting the exact timing of interventions in intra-day frequency data ex post. Second, we find that the lifetime of limit orders, i.e., elapsed time while listed in the order book, are affected positively by the size of volume, the gap between the quoted price and the market price, and a slower pace of the market. On the other hand, a larger set of outstanding orders on the order book shortens the lifetime of a new limit order. Finally, we find interventions, detected by the proposed methodology, significantly reduce the life-time of limit order in the market by about 27 to 44 seconds.

The remainder of this paper is structured as follows. The next section discusses the key concepts used in this paper and reviews the relevant studies in the literature. Section 3 describes the structure of the EBS dataset. Section 4 summarizes distinctive characteristics of the yen/dollar foreign exchange market on the day that the BOJ intervened for the first time in six years and reports preliminary investigations of the EBS dataset. Section 5 provides the empirical models and results. The final section discusses the findings and reports the conclusions.

2. Order flow, limit order, and intervention

In this section, we discuss the existing literature, with an emphasis on the relationship between three important features of this study: the use of limit orders as order flows, measuring the lifetime of limit orders, and an investigation of intervention at intra-day frequency. First, we argue that further investigation of the possible information dissemination role of limit orders is necessary. The current definition of order flow is based on actual transactions, i.e., observationally equivalent to market orders³. Second, the investigation of limit orders requires a new approach because, unlike market orders, most limit orders are canceled (or revised with a new price). We propose to investigate the effect of possible determinants of the life (i.e., the length of time that they remain in the order book) of limit orders. Third, using intra-day high frequency data for limit orders on the foreign exchange market, detection of the exact timing of intervention becomes an unavoidable issue⁴. Using an unusual, isolated incident of a publicized timing of intervention by the BOJ, we test the accuracy of an

³ Market orders are orders matching the existing best quote in the market, and limit orders are orders set at specific prices, which may not be the same as the best quotes.

⁴ See Menkhoff (2010) for a current survey on the high-frequency analysis of interventions and Vitale (2011) for a theoretical model of interventions in a market microstructure model.

intervention-timing candidate found using a proposed approach and intend to apply the same approach to other interventions if the approach is proven valid. In the following , we discuss the three key concepts used in this paper in turn: the relationship of order flow to market and limit orders, the life-time of limit orders, and interventions at intra-day frequency.

The relationship of order flow to market and limit orders

The microstructural approach to the foreign exchange market (e.g., Lyons, 1997) emphasizes the role of order flow as a determinant of the exchange rate. Order flow is defined as the net result of buyers' initiated transactions minus sellers' initiated transactions (Evans and Lyons, 2002b). Because customer transactions are private dealer information, order flow in interbank transactions disseminates this information and affects the market price. Acquiring proprietary order flow data from one of the largest market makers, Cerrato et al. (2011) and Marsh (2011) investigate the effect of order flows of various customer types on exchange rate. Order flow is found to affect exchange rate by reflecting macroeconomic information (Rime et al., 2010 and Frömmel et al. 2011) and commodity price (King et al., 2010). In this context, market orders are treated as the only tool conveying private information throughout the market, whereas the role of limit orders is considered to be only passive, at best providing liquidity to the market.

However, current foreign exchange markets, which are dominated by electronic brokering platforms such as EBS and Reuters, are limit order markets. Cumulative limit orders constitute the order book with best bid-ask quotes, and submitted market orders are matched with existing limit orders at the best quotes. The number of limit orders submitted exceeds that of market orders in various financial markets. The theoretical framework in which limit order traders act only as liquidity providers is not suitable for explaining the current limit order markets.

Theoretical models have been developed to allow a trader to choose between market and limit orders, e.g., Cohen et al. (1981), Foucault (1999) and Bloomfield et al. (2005), among others. Unlike market orders, limit orders face the risk of non-execution. Foucault (1999) examines the sub-game perfect equilibrium in a dynamic limit order market in which a trader chooses to submit either a market or limit order, with explicit consideration for non-execution risk and the risk of being picked off (or free-option risk). The results show that high volatility leads to more limit orders than market orders being placed and to a lower fill rate, i.e., the probability of being hit by a market order, for a limit order. Considering the two types of traders in a model, Bloomfield et al.

(2005) show that informed traders and liquidity traders use both market and limit orders. Informed traders, in particular, use market orders to realize profit at the opening of the market and switch to limit orders as the market price approaches true value at the close of the market.

Based on theoretical developments regarding limit orders, we argue that the limit order has a more active role in disseminating private information to the market than market orders⁵. In this paper, therefore, we define order flow as the bid limit orders minus the offer limit orders. We investigate whether the order flow defined by limit orders has a significant effect on the market price on the foreign exchange market.

Life-time of limit orders

Limit orders by their nature need not be executed instantly and are frequently canceled without any transaction taking place. Many studies document high levels of cancellations in various limit order markets. Biais et al. (1995) is the first to investigate the order book of the limit order market at the Paris Bourse, which provides traders with the best five quotes and the corresponding volumes each time a new order or cancellation occurs. They document that approximately 20 percent of orders (at best five quotes) are canceled⁶. Harris and Hasbrouck (1996) document that 56.2 percent of limit orders on the New York Stock Exchange remain unfilled. This figure should not be interpreted as active cancellation, as some limit orders simply remain unmatched at the close of the market. Using the complete tick data for a company on the Stockholm Stock Exchange, Hollifield and Miller (2004) report that the execution probability for two days is 68, 33, and 12 percent for limit orders that are, respectively, 1, 2, and 3 ticks away from the best quote. Eventually, 88 percent of limit orders with prices 3 ticks away from the best quote are canceled. Yeo (2005) reports that the ratio of cancellations to submitted limit orders on the New York Stock Exchange has recently increased to 40 percent⁷. Hasbrouck and Saar (2002) document that roughly 25 (40) percent of limit

⁵ The effects of limit orders on market characteristics are also investigated empirically and theoretically. As an empirical work, Biais et al. (1995) find that the conditional probability of placing limit orders rather than market orders is larger when the bid-ask spread is large or the order book is thin. In the model of Foucault et al. (2007), in which limit order traders possess asymmetric information about future volatility, the bid-ask spread signals the size of future volatility.

⁶ This percentage is calculated by the ratio between unconditional new orders and cancellations shown in Table III (p. 1670, Biais et al., 1995).

⁷ Yeo (2005) compares the percentage of cancellations in all submitted requests, which

orders are canceled after two (ten) seconds on the Island ECN, which constitutes 11 % of the trades on the Nasdaq exchange in 1999.

This large number of canceled limit orders can be attributed to the order splitting strategy and undercutting, according to Yeo (2005). Traders split orders in multiple submissions when they intend not to disseminate their private information. This strategy results in multiple cancellations when traders revise their orders. On the other hand, traders who compete to undercut other traders need to revise their prices frequently. The dynamic limit order market model of Foucault (1999) indicates that higher volatility leads to a lower fill rate. A lower fill rate, then, can be interpreted as a higher probability of cancellation in the foreign exchange market because no specific closing time exists. Foucault et al. (2005) theoretically show that the average time to a transaction increases with the size of the spread. This result in turn can be interpreted as indicating a lower fill rate at a fixed time interval during sporadic incoming orders.

To investigate why a significant proportion of order activities consists of cancellations and revisions, Fong and Liu (2010) consider the effect of non-execution risk, free-option risk, and monitoring cost in the order strategy. They find that both a closer submitted price to the best bid-ask quotes and a larger order volume increase the likelihood of cancellation or order revision. Using probit analysis, Yeo (2005) finds that a move in the market quote away from the submitted price induces cancellations. Both a larger volume in limit order and a larger volume at the best quote, i.e., the depth at quotes, deter cancellations.

Intervention at intra-day frequency

The availability of intervention data at intra-day level for the Swiss National Bank (hereafter SNB) motivates the research by Fischer and Zurlinden (1999), Payne and Vitale (2003), and Pasquariello (2007), among other studies. Using tick by tick data directly, Fischer and Zurlinden (1999) find that intervention, especially the first transaction, affects the exchange rate movement. Payne and Vitale (2003) also examine the SNB interventions by aggregating tick data at 15-minute intervals, whereas Fischer and Zurlinden (1999) used irregularly spaced tick series. They find that the SNB intervention has a stronger impact when it is leaning with the wind and concerted with other central banks. Pasquariello (2007) further aggregates tick by tick data into daily

include market orders, limit orders, and cancellations. Note that this percentage has the highest limit of 50 percent for cancellations because the number of cancellations cannot exceed the number of limit orders. Approximately 20 percent of orders were cancellations in 2001, compared with 5 percent in 1990.

variables.

Chari (2007) combines the news reports of interventions with tick by tick quotes from Reuters and finds that the BOJ and the FRB interventions lead to increased volatility and a widening of bid-ask spreads. Using hourly aggregates of tick data for the Czech krouna-euro, Scalia (2008) finds that interventions (news) by the Czech National Bank increase the impact of order flow on the exchange rate. In contrast, by aggregating tick data for the Russian rouble-US dollar into 30-second intervals, Melvin et al. (2009) find that the price impact of order flow is smaller on intervention days.

The exact timing of interventions can be traced back to headline news reports (e.g., Chari, 2007); however, the inaccuracy of news reports regarding interventions is well documented in Klein (1993), Osterberg and Wetmore Humes (1993), and Fischer (2006). Among the central banks making their daily intervention data available to the public, only the SNB reveals to her counterpart that transactions are carried out for the purpose of intervention, see Fischer (2006) for detail. The exact time in minutes can be confirmed only for SNB interventions. Regarding the interventions of other central banks, researchers may make educated guesses about the exact timing of particular intervention episode by gathering newswire reports and scrutinizing the tick data but are never able to confirm whether their guesses are correct. Notwithstanding this vagueness about the timing of interventions, on a single occasion (September 15, 2010), the Minister of Finance publicly revealed the exact timing of a BOJ intervention, see footnote 1. This incident provides a great advantage to BOJ intervention research, and we use this fact to its full extent to check the validity of our proposed methodology to detect the timing of interventions.

3. The EBS data structure

Traders can either initiate a quote (i.e., submit a limit order) or match a posted quote (i.e., submit a market order). In the EBS dataset, all data entries are assigned one of five indicators: QS, QD, HS, HAD, and DSM. A quote begins with QS and a specific 20-digit ID and ends with QD. A hit begins with HS and ends with HAD. When two parties are matched in a transaction, DSM records the information for the transaction. The life of a quote can be described by the four cases shown in Figure 1: (1) a quote is deleted by cancellation; (2) a quote is filled either by another quote or by a market order; (3) a quote is canceled after part of the order is executed; (4) a quote is filled by multiple transactions. In the EBS dataset, which we purchased with a limited contract, all data cannot be made public unless aggregated to conceal the characteristics of individual transactions.

4. Summary of trading activities on September 15, 2010

The dataset is all limit orders in the EBS JPY/USD spot market with the sample covering the period between 21:00:00 (GMT) on September 14 and 20:59:59 (GMT) on September 15. The number of all limit orders is 625,725. A large portion of orders is submitted literally within a split second after the last order has been placed in the market. The orders submitted within a second after the last order constitutes 97.3 percent (608,793) of all orders for the day. In addition, approximately 0.7 percent of all orders are submitted simultaneously, measured in terms of milliseconds, with another order. This extremely fast speed of orders is explained in part by the pervasive use of algorithm trading using computers⁸. The asymmetric information models described in Easley and O'Hara (1987, 1992) suggest that large orders and short durations are evidence of trading by informed traders. Manganelli (2005) find supporting evidence for the link between short durations and trading by informed traders on the NYSE.

4-1. Order volume and rate by minute intervals

In the sample period of 24 hours, the number of limit orders is 625,725, time-stamped in milliseconds. Due to the irregular time spans of quote submissions, interpreting a series of raw data requires special care, even for a simple graph. We choose to convert these raw quote data to minute intervals. The minute interval sums all volumes for limit orders submitted within one minute. For example, the volume for 23:02 covers all transactions processed between 23:02:00 and 23:02:59. The minute interval rate is the rate for the earliest limit order in the next minute. If no limit order is submitted in the current minute, the previous minute interval rate is maintained.

Figure 2 provides the simultaneous limit order volume and JPY/USD rate. The beginning of swift intervention by the BOJ near 1:00 (GMT) is obvious in the figure, although a smaller BOJ intervention before this time cannot be ruled out. Limit order volume for the 01:32 minute interval increased suddenly to 4,235 million US dollars from 167 million US dollars in the previous minute interval. In approximately ten minutes, the JPY/USD rate increased from 82.915 (mid-rate) at 01:31 (minute interval) to 83.835 (mid-rate) at 01:40 (minute interval). The Japanese yen continued depreciating and remained at approximately 85.70 at the end of the day.

⁸ Corwin and Lipson (2011) distinguish program (algorithm) traders, institutional traders, retail traders, and member traders in their empirical analysis of NYSE-listed securities. See Section 2 of their paper for the significant presence of program traders.

4-2. Hourly order size by order type

The order size in the dataset ranges from a minimum of one million US dollars to a maximum of 430 million US dollars (Figure 3). The size of orders used most is the minimum requirement of one million US dollars, and the use generally declines with increasing size of orders except for some focal numbers such as 10 million. The clustering in small orders is consistent with the limit of open positions for traders (Cheung and Chinn, 2001). The intraday position limit of most dealers in the US does not exceed 50 million US dollars. Cheung and Chinn (2001) report in their survey that 54 % (74 %) of dealers are authorized to have a maximum open position of less than 25 (over 50) million US dollars. Orders exceeding 50 million US dollars are exceptionally high against the limit of open positions for the most trading institutions. For the intervention days in the pre-crisis period, the maximum volumes of limit orders are 100, 520, 500, 500, and 300 million US dollars, respectively, for September 12, 2003; September 30, 2003; December 10, 2003; January 9, 2004; and March 5, 2004.

Based on the transaction data reported in Figure 2, there is substantial variation in the activity of the foreign exchange market, especially on the intervention day. In this subsection, we break down the market orders by hour and compare the characteristics of orders between limit and market orders and between offer (sell) and bid (buy) orders. Table 1 reports the number of orders submitted in a particular one-hour period. Consistent with the transaction volume reported in Figure 2, panel (A) in Table 1 indicates that the number of orders exceeds 47,000, i.e., there were approximately 13 orders per second after 01:00, and the trading continues to be highly active until 15:00. In terms of dollar purchase interventions by the BOJ, the frequency of order type does not hint at any peculiarity possibly caused by the official intervention.

Panel (B) in Table 1 provides the hourly breakdown of order size on the foreign exchange market. The average size of orders varies from 1.14 million US dollars at 17:00 to 2.09 million US dollars at 21:00. It is noteworthy that the average volume of 1:00 (the start of the sharp depreciation of the Japanese yen) takes place within the high part of the range at 1.49 million US dollars. The maximum volumes per orders are 430, 411, and 300 million US dollars, respectively at 12:00, 8:00, and 1:00.

We further investigate order activity by examining the hourly breakdown of order size by market order types in Panel (C) in Table 1, which provides the number of orders greater than or equal to 10 and 50 million US dollars for bid, offer, and both. Focusing on the three most active orders in each category, the orders at 1:00, 2:00, and 7:00 show quote activities that are active in high-volume orders. In these high-volume

order categories, the number of bids exceeding offers is observed at more hours.

5. Empirical analysis

5-1. Exchange rate change and order flow

The effect of order flow on price change is well documented (Jones et al., 1994, Evans and Lyons, 2002). In the literature, the net order flow is the difference between purchase orders and sales orders. Distinguishing intervention days from non-intervention days, Marsh (2011) estimates the effect of net order flow on the change in the exchange rate. Interestingly, the significant effect of order flow on non-intervention days disappears on intervention days.

The net order flow is constructed for minute intervals between 21:00 on September 14, 2010 and 20:59 on September 15, 2010. As discussed in detail in Section 2, we define the net quote order flow as the bid limit order (dollar purchase) minus the offer limit order (dollar sales), and a positive value indicates a net purchase order for dollars. Figure 4 shows the net order flows of yen/dollar spot foreign exchange market on the EBS by minute. The US dollar purchase order by the BOJ intended to depreciate the Japanese yen should appear as a positive value in the figure.

Plotting the net order flow against the change in exchange rate in Figure 5, we observe a positive relationship between the net dollar purchase and a positive return of the yen/dollar exchange rate. More formally, following the simple regression approach in Marsh (2011), we estimate the following equation (1):

$$R_t = \alpha_0 + \alpha_1 OF_t + \varepsilon_t, \quad (1)$$

where R_t is the change in the log of the exchange rate at minute intervals (used in Figure 2), and OF_t is the net order flow by minute.

The upper panel of Table 2 reports the estimation results for September 15, 2010. The coefficient of net order flow is correctly signed and statistically significant at the one-percent level. The fitness of regression in terms of adjusted R^2 is 0.31 and is relatively high compared to the order flow literature. It is noteworthy that order flow in previous studies is defined using market orders (or observationally equivalent transactions).

We also estimated equation (1) for the five intervention days in the pre-crisis period. The estimation results are shown in the lower panel of Table 2. The coefficients of order flow are all statistically significant at the five-percent level, but the degrees of

fitness of the regression are smaller than that for the post-crisis period. In this study, we obtain supporting evidence that the limit order version of order flow also affects the price. This result supports the notion that the submission of a limit order carries important private information to be disseminated through the market.

Stability of the relationship between order flow and exchange rate and intra-day intervention detection

Now, reflecting the fact that previous studies using daily exchange rate data and daily order flow data can distinguish intervention days from non-intervention days as in Marsh (2011), we test whether the parameters of the empirical model in equation (1) is stable throughout the entire period including pre-intervention hours, intervening hours, and post-intervention hours. For this examination, we implement the CUSUM test for the residual from the regression of equation (1). The cumulated sum of the residuals is plotted along the 95 percent upper-bound and lower-bound lines in Figure 6. The structural change is first detected at the 95 percent level at 02:03 on September 15, 2010. It is noteworthy that the cumulated sum of the residuals begins a sharp increase near 01:30. We have evidence that the relationship between the order flow and exchange rate returns is affected by the BOJ interventions.

The cumulated sums of the residuals are similarly plotted for five intervention days in the pre-crisis period in Figure 7. Strikingly, the standard CUSUM tests do not reject the null hypothesis of no structural change occurring during the pre-crisis period except for September 30, 2003 in Panel B of Figure 7. On September 30, 2003, the cumulative sum of the residuals exceeds the 95 percent upper bound at 23:25 (GMT).

What is striking in these plots of the cumulative sum of residuals and the cumulative sum of squared residuals is that sudden increases are observed, almost vertical increases, at several points in the sample. Three occur on September 15, 2010, one on September 12, 2003, three on September 30, 2003, two on December 10, a less obvious one on January 9, 2004, and at least two on March 5, 2004. These plots indicate that unusually high volume orders by the BOJ interventions can be detected at the minute or at least hour level by plotting the cumulative sum of the residuals. This reflects the fact that the relationship between limit order flow and exchange rate drastically changes when the BOJ is intervening in the foreign exchange market.

5-2. The lifetime of limit orders on the EBS platform

After a limit order is submitted to the market by a dealer, the order waits to be hit by other dealers for a transaction to occur. The life of limit orders can be categorized

into three cases: (1) the total volume of a limit order is filled by a transaction(s); (2) the limit order is canceled before any transaction is realized; (3) the limit order is withdrawn after a part of the volume ordered is transacted.

Microstructure models for foreign exchange markets emphasize the importance of order flow because of its explanatory power with regard to exchange rate fluctuations. For example, Evans and Lyons (2002) assume that customers initiate trades with dealers at the prices they quote and that these customer orders are private information. Then, dealers trade amongst each other and, at this interdealer stage, the private information contained in customer orders is materialized in order flow. This function of interdealer order flow to aggregate dispersed information serves to affect exchange rates.

However, the microstructure literature implicitly assumes that all limit orders are completely transacted and does not address the issue of cancellation. This misses a substantial part of dealer behavior because limit orders that are canceled without any transactions comprise more than 80 % of all orders⁹. If order flow, i.e., orders realized through non-zero transactions, transmits important information among dealers, what pieces of information do canceled orders carry to the market?

Moreover, what underlying features influence the behavior of dealers toward cancellations of orders? Two of the most probable reasons to these questions are discussed below. First, adjusting the mispricing of quotes becomes necessary if the market price moves away from one's own quote¹⁰. Second, adjusting quotes sequentially may be a strategy followed by dealers. The adjustment for mispriced quotes is not intended to refer to the first quote, but orders may be submitted intentionally with quotes slightly away from the intended price. This pricing behavior can be thought as the hybrid of a (pure) limit order and a market order. On the one hand, a market order has an advantage of executing instantaneously; however, it misses a possibly better deal. On the other, a (pure) limit order can be set at a price better than a market order; however, it may never (at least for a few hours) realize a transaction, see Cohen et al. (1981). For liquidity constrained dealers, sequentially quoting may be the best mix of these two extremes. Bloomfield et al. (2005) observe a case, from an experimental study,

⁹ Biais et al. (1995) reports that only approximately 20 % of orders are canceled in the Paris Bourse, but they only observed cancellations at the best five quotes. The smaller figure in their studies results from the fact that cancellations outside the best five quotes are unnoticed.

¹⁰ Leaving a mispriced quote in the market does not cost dealers and such quotes need not be canceled immediately. However, submitting a new quote with correct pricing may reach the credit ceiling of dealers or exceed the maximum risk exposure. This submission of a new quote makes the cancellation of existing mispriced quotes necessary.

in which both liquidity and informed traders later cancel limit orders.

How can mispriced quotes be distinguished from sequential quotes in empirical data? One important feature is the duration of canceled quote in the market. For a mispriced quote, it is likely to take a longer time to become necessary to make an adjustment than with a sequential quote strategy, especially during a less volatile period. Sequential quotes are likely to be submitted for prices further away from the current best bid and offer quotes, *ceteris paribus*. Moreover, reinterpreting the result of a lower fill rate with high volatility (see Foucault, 1999) in the context of continuous-time trading in the real world, a limit order is likely to remain on an order book for a longer time because of the lower probability of being hit by market orders.

Constructing the dataset and variables

Each limit order, when submitted, is identified with a distinguishing 20-digit code alongside (i.e., bid or offer), volume, quoting price, and time stamp in the slice of a second. The dataset also records all market orders and transactions realized.

Each limit order reappears in the dataset when all volume is exhausted by transactions with other dealers or when the order is canceled. A limit order is time-stamped when entered into and removed from the order book. The duration of limit orders is then calculated from the difference between the two time stamps. The duration we calculated in this study needs to be distinguished from the duration studies in which the time elapsed between two consecutive quotes is measured, e.g., Manganello (2005).

Because of the nature of this EBS database, unlike the best orders in both bid and offer in the dataset readily constructed by ICAP, we needed to reconstruct the order book, adjusting each time with a submitted quote, a transaction, or a cancellation. By reconstructing the entire order book for the sample period, we were able to calculate the best bid, the best ask, and the bid-ask spread corresponding to the tick-time-series.

Using a quote price recorded in the original dataset and the constructed best-bid and best-ask price, we calculated the price gap, Gap_i , between an individual quote and the best quote at the time of the quote submission. This gap or distance should reflect the degree of the liquidity motive. On the one hand, if a dealer needs her submitted order to be executed rapidly, this gap must be small. On the other, if a dealer expects her order to be placed at a more advantageous price with a risk of the transaction not occurring, this gap becomes large.

Using the constructed order book, we aggregate the volume of standing orders within 5 ticks, i.e., 0.05 yen, of the best price on both sides as a measure of the market depth, $Depth_i$. The market depth should affect the behavior of dealers, especially

regarding the timing of canceling a submitted order.

To measure the calmness of the market, the time span for the previous 20 limit orders is calculated. This measure, $Calm_i$, is proportionally the reciprocal of the number of limit orders within a fixed period. The larger this measure is, the slower the trading activity in the market is. When the market is fast paced, the decisions and responses of dealers need to be accelerated. Table 3 summarizes the descriptive statistics for these variables.

Estimation models and empirical results

For each limit order i , clock times are measured at the start of order, $t^s(i)$, and at the end of order, $t^e(i)$. The volume and quote are recorded as v_i and q_i . The best bid and ask (offer) are time-varying and are $b(t)$ and $o(t)$, respectively. I_i is an indicator function, taking the value of one for bid orders and zero for offer orders. The order book is kept as the sum of the volume at the rate by each tick, by 0.01 yen, on the bid and offer sides, $bv(t, rate)$ and $ov(t, rate)$, respectively.

$$d_i^{se} = \beta_1 Vol_i + \beta_2 Gap_i + \beta_3 Depth_i + \beta_4 Calm_i + \varepsilon_{t^s(i)} \quad (2)$$

where $d_i^{se} = t^e(i) - t^s(i)$, $d_i^{ss} = t^s(i) - t^s(i-1)$, and ε_i is independently and identically distributed. Four independent variables are defined as follows: $Vol_i = v_i$,

$$Gap_i \equiv I_i |b(t^s(i)) - q_i| + (1 - I_i) |o(t^s(i)) - q_i|,$$

$$Depth_i \equiv \sum_{j=b_i-0.04}^{b_i} bv(t^s(i), j) + \sum_{j=o_i}^{o_i+0.04} ov(t^s(i), j), \text{ and}$$

$$Calm_i \equiv \sum_{j=i-19}^i d_j^{ss}.$$

The estimation results for equation (2) are shown in Table 4. The lifetimes of all limit orders are calculated, except for the first 29 instances due to the reconstruction of the order book to recover the best bid and ask quotes. The lifetime of these limit orders are regressed on four independent variables. All estimated coefficients are statistically significant at the one percent level. First, larger individual order volumes affect the order lifetime positively. As discussed in Section 4-2 and shown in Figure 4, most limit orders are submitted at a minimum size of one million US dollars. The

estimated coefficient indicates, when other effects are controlled for, that minimum volume orders leave the order book within ten seconds (9.898 seconds) on average. Second, the larger the difference between the quote and market prices, the longer a limit order stays in the order book. If a quote price is 0.01 points away from the market price, the additional lifetime of a limit order is approximately 26 seconds. Third, market depth hastens the exit of a limit order from the market. The more orders are stocked in the order book, the more rapidly a limit order disappears from the market. Note that an infinitesimal increase, i.e., 1 million US dollars, in the order book does not have a large effect. An additional 100 million US dollars shortens the lifetime of limit orders by approximately 18 seconds. Fourth, the calmness (the reciprocal of volatility) of the market allows a limit order to stay longer in the order book. At the mean value of the Calm variable (2.15 from Table 3), a limit order stays approximately 11 seconds in the order book on average.

The estimation may be biased if both hit orders and canceled orders are included in the same sample because the former is more likely to represent orders with quotes close to a contemporaneous market price and thus has a shorter life time. We also investigate the empirical model of equation (2) using only canceled limit orders, and the results are shown in the third and fourth columns of Table 4. The qualitative results are very similar to those of the sample including all limit orders.

To shed light on the empirical question of whether the global financial crisis affects the behaviors of foreign exchange market, we repeat the same exercise for the five different days on which the BOJ interventions took place. We note that both the changes in the overall market behavior due the global financial crisis and the different effects of long-forgotten interventions may cause different response patterns in the estimation results between samples recorded during the pre- and post-crisis periods. In Table 5, the qualitative results of the sample recorded before the crisis in terms of the degree of fitness of the regressions, statistical significance, and the signs of the coefficients are quite consistent with those of the sample after the crisis, except for the positive coefficient of $Depth_i$ on Apr 9, 2004.

By comparing the range of the estimated coefficients in the pre-crisis period with those in the post-crisis period, we find that the coefficients of Gap and Calm in the post-crisis period fall outside of those in the pre-crisis period. For Vol, the estimated coefficients range from 4 to 31 in the pre-crisis period, and 9.898 (all orders) and 13.316 (canceled orders) in the post-crisis period lie within the range. For Depth, the estimated coefficients range from -0.7 to 0.14, and -0.182 (all) and -0.217 (canceled) also lie within the range.

However, for Gap, the effect of quote prices deviating from the market price on the life of limit orders is approximately half of the minimum value of the range in the pre-crisis period. This implies that limit orders on Sep 15, 2010 were withdrawn from the order book much faster than during the pre-crisis period. No-execution risk and foregone opportunity cost are much higher in the market after the crisis.

Comparison of the estimated coefficients of Calm shows that a slower-paced market condition during the post-crisis period allows limit orders to enjoy positions in the order book for longer periods. In other words, the relative exiting decision time from the order book is shorter in the market during a volatile period than a calm period after the crisis.

5-3 *The effect of intra-day interventions on limit orders*

Given the significant change in the magnitude of forecast errors plotted as cumulated sum of residuals in Figure 6 at the same timing as the announced official intervention by the BOJ on September 15, 2010, we propose to construct an intervention proxy variable at minute intervals. This (intermediate) intervention variable takes the value of one when a forecast error from the regression in equation (1) exceeds the threshold value and zero otherwise. We only account for large positive errors in this study because all interventions are US dollar purchase, but for a general case of interventions in both directions forecast errors in absolute terms should be applied. The threshold values are chosen to at least cover the obvious intervention timing of around 1:30 (GMT) and not include too much portion of the entire sample. These values are 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0. By this way, each minute interval is assigned to either one or zero. The number (the percentage) of minutes assigned the value of one is 260 minutes (18.1%), 134 (9.3%), 85 (5.9%), 49 (3.4%), 32 (2.2%), and 23 (1.6%), respectively for the threshold values of forecast errors being 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0.

These binary classification based on minute interval is then applied to tick-base limit orders at the submission time. If a limit order is submitted in a minute interval at which the forecast error from order flow regression exceed the threshold value, $INTERV_i$ takes the value of one and zero otherwise. The equation (3) is estimated with the tick data on September 15, 2010.

$$d_i^{se} = \beta_1 Vol_i + \beta_2 Gap_i + \beta_3 Depth_i + \beta_4 Calm_i + \beta_5 INTERV_i + \varepsilon_{t^s(i)} \quad (3)$$

In Table 6 the estimated results of equation (3) is presented. The result of

equation (2), without $INTERV_i$ variable in equation (3), is provided as specification (i) for comparison. Specification (ii) through (vii) include an intervention dummy variable, $INTERV$, which takes value of one when a forecast error exceeds respectively the threshold value of 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0. First, $INTERV$ variable is statistically significant for all specifications. The magnitude of impact, when interventions (and lingering post-intervention effect) are observed in the market, is the reduction of about 27 to 44 seconds in the life-time of limit orders. This is consistent with the result in Fong and Liu (2010) that limit order cancellations and revisions increase with the market volatility. Second, the magnitude of impact on reducing the life-time is monotonically larger when the threshold for forecast errors becomes greater. The greater volatility in exchange rate caused by interventions affects existing orders to be canceled or revised. Third, a relatively moderate size of threshold, i.e., specification (iii) is chosen best for our model by the Schwarz BIC. For this specification, only 9.3 percent of the entire sample is designated as interventions or post-intervention effects. Finally, we note, however, the increase in terms of overall fitness of regression is only marginal.

6. Conclusions

In this paper, we investigate the impact of the BOJ intervention on September 15, 2010 on trading activities on the yen/dollar market of the EBS. The BOJ had refrained from interventions for more than six years and the world is hit severely by the global financial crisis during this period. We also investigate five intervention days that occurred in 2003 and 2004.

Given the major role of limit orders on the EBS, it is imperative to investigate the effect of limit orders on the foreign exchange market. Contrary to previous studies, the net order flow in this study is constructed from limit orders rather than from market orders, which are observationally equivalent to transaction data. The main contributions of the investigation on the relationship between order flow and exchange rate are the following two points. First, we find that the order flow of limit orders has a positive impact on the exchange rate, i.e., an excess of bid over offer orders appreciate the value of the US dollar against the Japanese yen. This is consistent with many previous studies which use the market order (transaction) definition of order flow. Second, we find that the relationship between order flow and market return on the dollar/yen exchange market experiences a structural change following the unexpected and very high volume of offer/sell orders following the BOJ interventions. The cumulative sum of residuals detects the timing of the BOJ interventions with striking clarity.

Using the EBS data provided by the ICAP to track the end of limit orders, we

measured the lifetime of limit orders. We find that the volume, the gap between quote and market price, and the slower pace of the market all contribute to a longer stay of limit orders on the order book whereas large outstanding orders in the order book shorten the lifetime of new limit orders.

Finally, a simple methodology is proposed to detect the exact timing of interventions. We propose to construct an intervention proxy variable which takes the value of one when a forecast error from the order-flow-exchange-rate regression exceeds the threshold value. We find interventions, detected by the proposed methodology, significantly reduce the life-time of limit order in the market by about 27 to 44 seconds.

Figure 1. Records of quotes on the EBS Spot market

Note: QS indicates the start of the quote. QD indicates the end of the quote. DSM indicates a transaction. There are four cases for the life of quotes. (1) a quote is deleted by cancellation; (2) a quote is filled with either another quote or a market order; (3) a quote is canceled after a part of the order is executed; (4) a quote is filled by multiple transactions.

Figure 2. Exchange rate and limit-order volume plotted against minute interval

Note: The minute interval sums all limit order volumes in a one minute period. For example, the volume at 23:02 covers all transactions that occur between 23:02:00 and 23:02:59. The minute interval exchange rate is the mid-rate of the latest best bid-ask rates during the current minute. The exchange rate is scaled on the left vertical axis and the limit-order volume (bar) is scaled on the right vertical axis.

Figure 3. The distribution of order size

Note: All limit orders on the JPN/USD spot market from 21:00:00 (GMT) on September 14 to 20:59:59 (GMT) on September 15. The number of data points is 625,725. The vertical axis is the number of orders, shown on a log scale. The size of orders on the horizontal axis is marked in US million dollars. Over 85 percent of all orders have a minimum value of 1 million US dollars.

Figure 4. Quote order flow

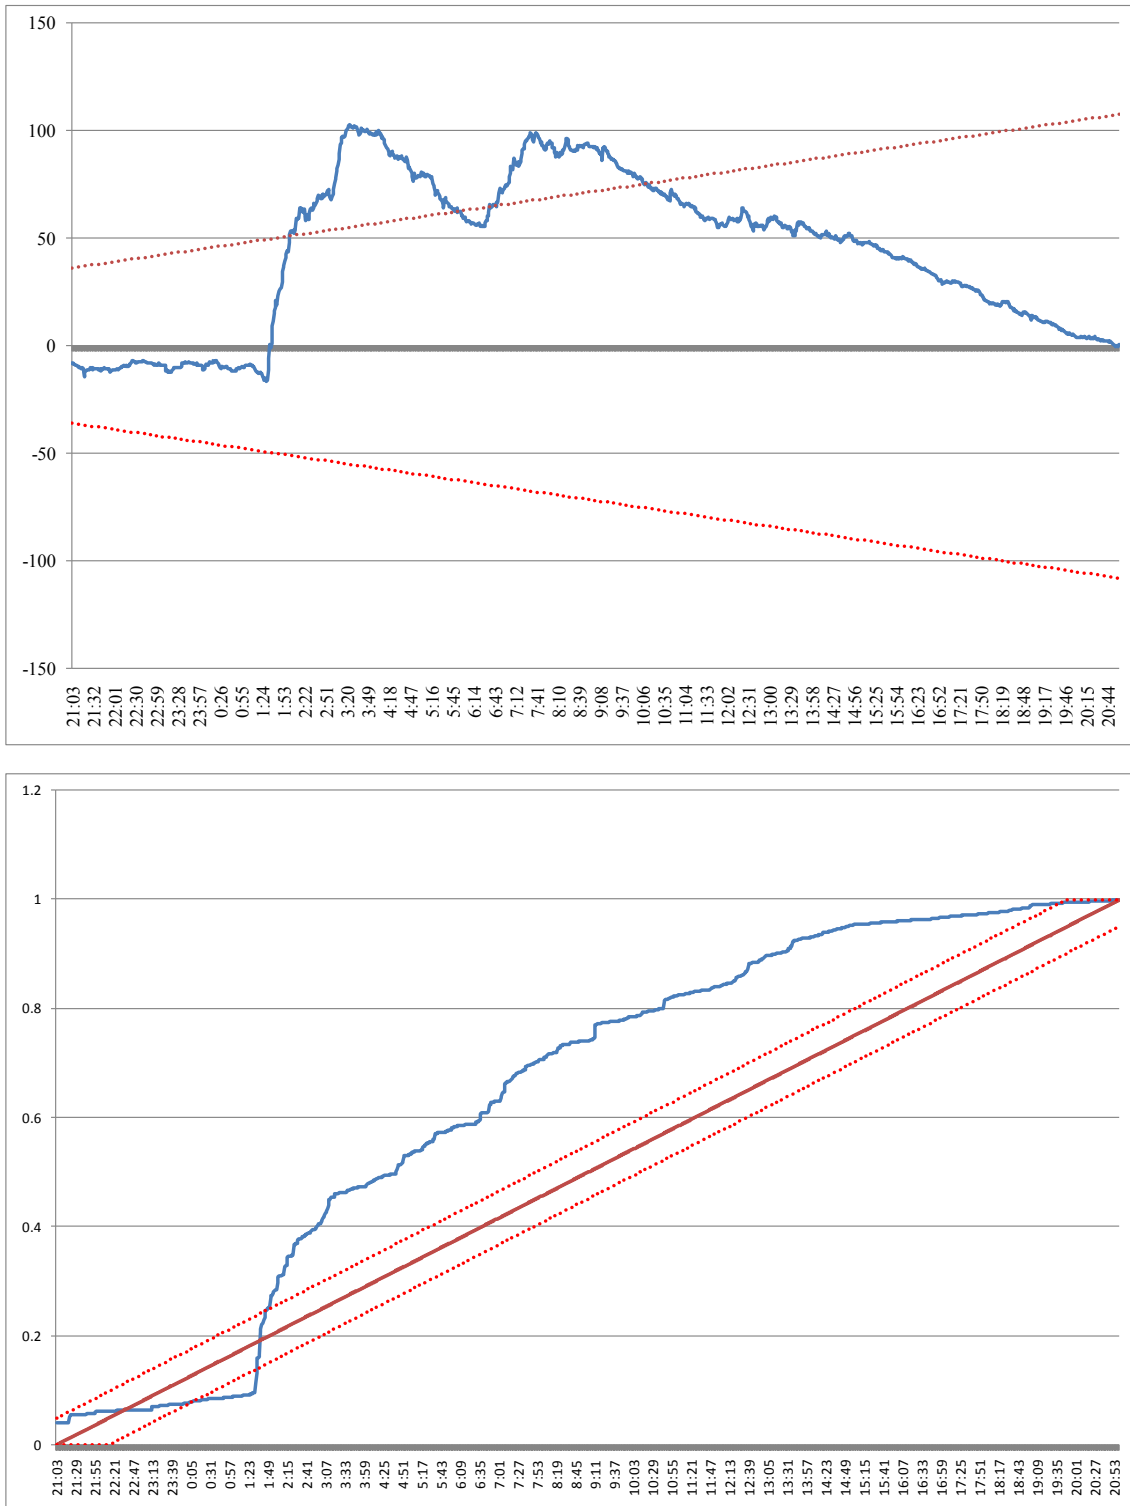

Note: The net quote order flow is defined as the bid (dollar purchase) minus offer (dollar sales). The minute interval sums all quote volumes for the one minute.

Figure 5. Exchange rate and order flow

Note: The one-minute change measured in log yen/dollar is plotted on the vertical axis, and the net (quote) order flow is plotted on the horizontal axis.

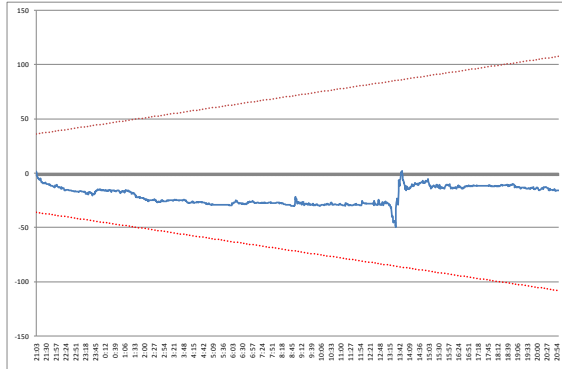

Figure 6. The CUSUM and CUSUM square tests

Note: The solid line represents the accumulated sum of the forecast residuals (upper panel) and the squared forecast residuals (lower panel), and the dotted lines represent the 95 percent upper and lower bounds.

Note: The figures in panels (A) and (C) are the number of orders submitted within one hour. In panel (B), the unit is one million US dollars for the average and maximum values. In panel (C), 10 over and 50 over represent the number of orders greater than or equal to 10 and 50 million US dollars, respectively.

Table 2. The per minute change in yen-dollar on net order flow

post-crisis		pre-crisis				
<u>2010Sep15</u>		<u>2003Sep12</u>	<u>2003Sep30</u>	<u>2003Dec10</u>	<u>2004Jan9</u>	<u>2004Mar5</u>

NOB	1439	1439	1439	1439	1439	1439

Note: The dependent variable is the per minute change in the log of the yen/dollar exchange rate, and a positive value indicates dollar appreciation. The net quote order flow is defined as the bid (dollar purchase) minus offer (dollar sales), and a positive value indicates the net purchase order measured in dollars. The standard errors in parenthesis are robust to heteroskedasticity. *, **, and *** denote statistical significance at the ten-, five-, and one-percent levels, respectively.

Table 3. Descriptive statistics

	<u>mean</u>	<u>s.d.</u>	<u>min</u>	<u>max</u>
d_i^{se} (lifetime of limit order)	41.9	526	0.001	85716
Vol (volume)	1.36	2.70	1	430
Gap (difference between the quote and market price)		0.0225	0.0696	-0.3
	33.5			
Depth (the volume sum in the order book)	178	86.2	4	845
Calm (previous durations for consecutive orders)	2.15	5.60	0.009	508

Note: The number of observations is 625,573, excluding the first 29 observations.

SBIC	4763180	4762950	4762930	4762940	4762980	4763020	4763040
NOB	625571	625571	625571	625571	625571	625571	625571

Note: The first 31 (not 29) observations are dropped for all specifications to have equal number of observations. The first specification is the same as in Table 4 except estimators are a little different due to the difference in the number of observations. Specification (ii) through (vii) include an intervention dummy variable, INTERV, which takes value of one when a forecast error exceeds respectively the threshold value of 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0.
